ACKNOWLEDGEMENTS

The author wishes to express his sincere appreciation to Professor R. W. Mann for his help and continued interest, and for his great patience through all stages of this project.

The author also expresses thanks to Mr. M. Burnstein and Mr. C. W. Christiansen for their help, and to the several companies, mentioned elsewhere in the text, for their cooperation in providing data and components for this project.

ABSTRACT

A prosthetic elbow has been built which satisfies or surpasses all NAS-CPRD criteria* for such devices, except the restriction to a 12 volt electrical system. The device provides proportional control of elbow torque from an electrical signal and also continuous self-locking so that no power is used to hold a load stationary. The proportional control signal to be used was assumed to be derived from muscle EMG output and control circuitry was designed accordingly, although any proportional electric input may be used. EMG control has the advantage of providing meaningful force feedback to the operator.

CHAPTER ONE
SYSTEM REQUIREMENTS

I. DESIGN OBJECTIVES

The Committee on Prosthetic Research and Development of the National Academy of Science has stipulated that a prosthetic device should not weigh more than 60% of the limb it replaced. Due to possible variation in the distribution of this weight from one device to the next, the arbitrary 60% figure may not always be appropriate. However, qualitatively, light weight is important. Carrying a small machine is very different from carrying a part of oneself of the same weight. An attempt was made to keep the device as light as possible while using standard industrial components throughout.

Of greater importance is the device's moment of inertia about it's degree of freedom; in this case the elbow. There are no quantitative criteria for this parameter but it also should be small. If possible, the actuator and drive train components should be located in the above elbow section. However, in order to accomodate possible very long upper arm stumps, It was necessary to keep the above elbow portion of the device as short

as possible, and therefore to locate this machinery in the forearm section. An electric motor and screw actuator were used. There are about $1\frac{1}{2}$ " of forearm length adjacent to the elbow which is unoccupied in flexion but is occupied by the upper arm section in extension. To make efficient use of this space, the screw end of the drive train must be adjacent to the elbow, with the motor toward the other end of the forearm section. Thus, the screw occupies the aforementioned space in flexion.

It was considered important to give the device a maximum speed approaching that of a normal elbow. To do this the device must either have very little reduction gearing, which sacrifices elbow torque, or must have relatively low friction losses. A low friction ball screw was used. The ball screw, having little friction, is not self locking so that holding a stationary load would require constant torque output from the motor, and consequent drain of power. To correct this deficiency a reverse locking clutch was placed between the motor and screw.

While the performance of this assembly is more than adequate, the clutch is too heavy for this application. The clutch is an industrial

unit rated at 90 in.-lb. torque and weighs almost a pound. The maximum torque output of the motor is 5 in.-lb. Primarily due to the clutch, the forearm moment of inertia about the elbow is nearly as great as that of a normal arm.

The use of EMG control signals was anticipated and an all electric system was built so that only one type of energy storage is required

For details, see appendix B

II. Explanation of Development

a) Efficiency and Power Requirement

The amount of energy that can be carried on one's person is severely limited. We used nickel-cadmium batteries, which are quite widely used, for energy storage. While these do not have as much energy per unit weight as other types, they are readily available and more economical. A realistic estimate of their energy is about 8 watt-hr./lb.

It is desirable to conserve energy with as efficient a device as possible. Major losses in most proportional control devices are:

Control circuitry-Efficiency may vary
between 0-80% depending on load
and operating conditions. average $e=50\%$

Motor-Varies between 0-70% depending
on type of motor and load. For permanent
magnet motor, average $e=40\%$

Gear reduction-Generally, $e=70\%$

Screw or worm gear actuator-For self
locking, the maximum theoretical
efficiency obtainable approaches
50% as μ approaches 0 (square thread)
Maximum practical efficiency is
in a porous bronze on steel unit
with 14° helix angle; $e=30\%$

In addition, because a high friction drive
train uses almost as much power when lowering a
load as when lifting, overall efficiency will
have to include an additional $e=50\%$

With all these factors considered and multiplied,
the average efficiency of devices now available is:

$$e=2\%$$

In contrast, the efficiencies which are possible
with presently available technology are as follows:

Control circuitry- With switching or
parametric power stages; $e=80\%$

Motor- Permanent magnet type run at
constant load; $e=70\%$

Gear reduction- $e=70\%$

Actuator- Ball screw with reverse
locking clutch; $e=90\%$

And because the ball screw actuator uses
no electrical energy in lowering a load, the

efficiency factor for two way operation; $e=90\%$

Overall efficiency of this well engineered device would be:

$$e=32\%$$

Efficiencies in the device developed during this project are;

Control circuitry- Switching power amplifier; $e=80\%$

Motor- Permanent magnet type; $e=40\%$

Gear reduction- $e=70\%$

Actuator- Ball bearing type with R-L clutch; $e=90\%$

Effective efficiency when lowering loads; $e=90\%$. The overall efficiency of this device is;

$$e=18\%$$

To illustrate the effect of efficiency , consider flexing the elbow with a five pound weight at the hand. The weight is raised about 2 ft., so the energy transfer is 10 ft.-lb., or .004 watt-hr. The number of times a five pound load can be lifted, per pound of batteries is:

$e=2\%$; 40 lifts/lb.(batteries)

$e=18\%$; 360 lifts/lb.

$e=32\%$; 640 lifts/lb.

In addition to conserving energy, the low friction drive train allows a range of performance

not previously considered practical, with high elbow output torque and high no-load flexion speed.

For details, see appendices B & E

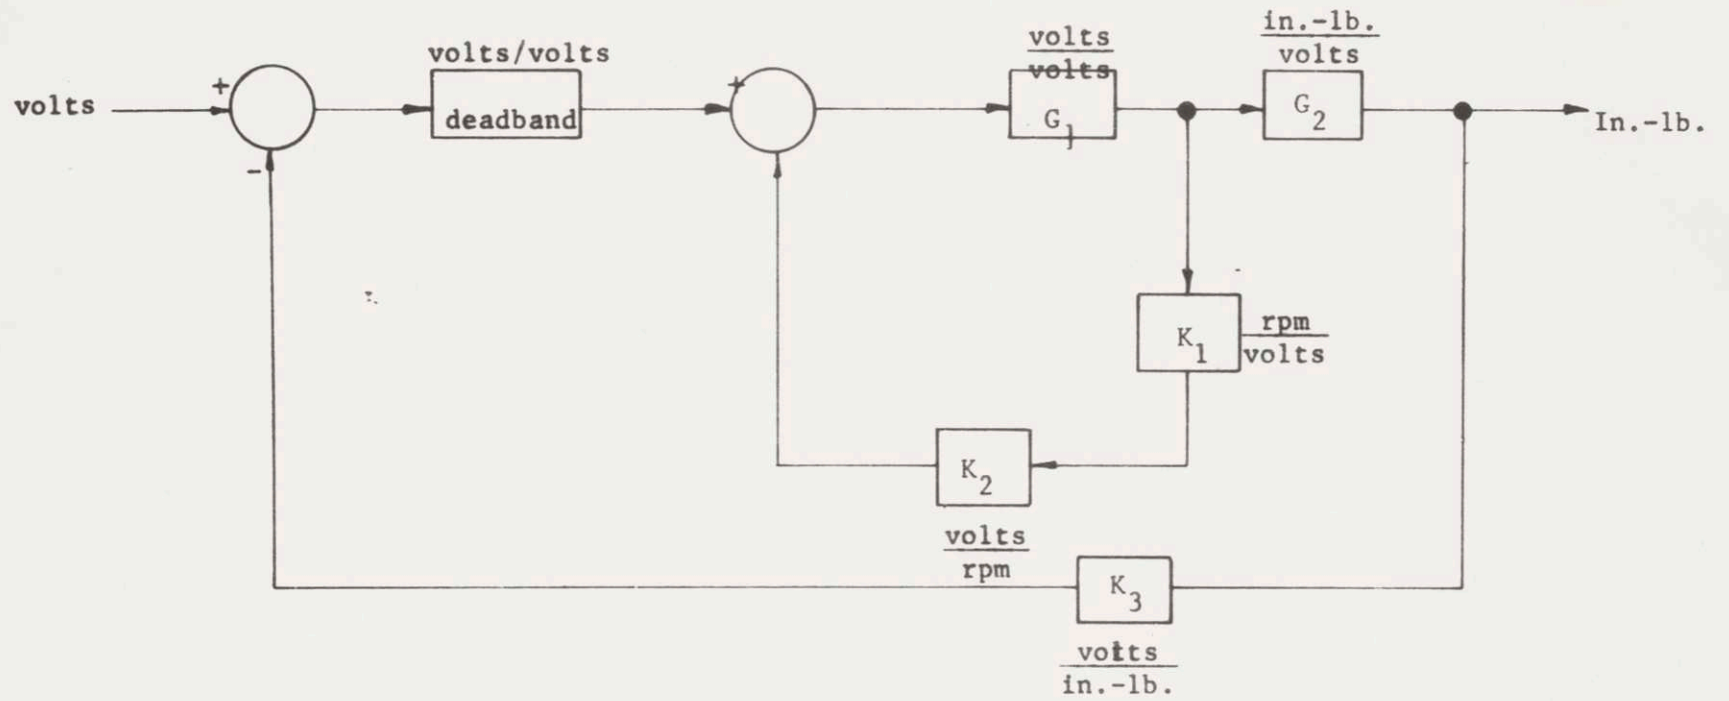

b) The Control System

This is a very straightforward system with a DC motor- actuator and DC input (see figure 3). Overall gain is 20-25 in.-lb. elbow torque per volt input.

Force feedback is included primarily to take advantage of the self locking feature of the drive train. With the output torque such that the force feedback signal is approximately equal to the input, the error is close to zero, within the deadband in the forward loop. Then the power to the motor is zero, and the output torque is sustained by the reverse locking clutch.

Velocity feedback was included as an afterthought. The motor has its own velocity feedback in the form of back EMF, but this was not found sufficient. Without the additional feedback slow motions were jerky due to starting friction, primarily in the motor gear train.

Force feedback is provided by a strain gauge bridge which measures the bending moment in the above elbow section. Velocity feedback is by

The Control Loop

figure 3

measuring and amplifying the motor back EMF.

For details, See appendices A, B, C, and D.

c) Permanent Magnet DC Motor

This is the lightest and most efficient type of electric motor available in the given power range (.01 hp.). In addition, it is reversible by changing the direction of the input current and has linear characteristics. As a result, this type is potentially the best fit for prosthetic requirements. However, if used over a wide range of speeds and loads, efficiency drops rapidly and current increases at higher loads. In addition to the power drain which this causes, the higher current tends to demagnetize the field magnets. Prosthetic use involves a very wide range of loads, varying from the weight of the device itself to that of a load being lifted. As a result, PM motors in prosthetic applications will have relatively short life. Before a reliable device can be produced, either a suitable replacement must be found for the PM motor, or this difficulty must be overcome by compensation of some sort.

For details, see appendix G

CHAPTER TWO

DESIGN CHARACTERISTICS

I. Design Deficiencies

a) Excessive Weight

The device weighs slightly over two pounds, which is considered too heavy for an above elbow prosthesis. It also has too much inertia for an external power device as lively as this one. Therefore, weight must be cut before the device is a practical prosthetic aid. This raises some problems since the standard motor and drive train components account for almost $1\frac{1}{2}$ lb.; the supporting structure is already about as light as it can be made. The reverse locking clutch accounts for almost one pound.

Considering the distribution of weight (primarily in the forearm section), the device must weigh under $1\frac{1}{2}$ lb. before it can be fitted on an amputee.

b) Circuitry is Expensive

Control circuitry for the arm was designed to be entirely dissipative, and components were therefore chosen for high power capacity.

However, circuit dynamics are such that the power amplifier is in fact a two state modulator. Efficiency is therefore increased, but the circuit design is wasteful in the number and cost of components used.

See appendix E for details.

c) Impedance Seen by Motor is Variable

The motor drives the arm via a constant reduction drive train composed of gear reduction, a screw actuator, and the arm linkage geometry. The choice of drive train ratios was dictated by the need to make the maximum operating speed of the motor correspond to a nearly natural maximum flexion speed. Since the gear reducer and screw are available standard in certain fixed ratios, the geometry was chosen to provide 180 deg./sec. flexion speed at 18,000 rpm motor speed. As a result, the load seen by the motor when the arm is lifting five pounds is five times as great as when lifting one pound (no external load). Therefore, the high efficiency of the PM motor is taken advantage of only at very light loads.

With higher loads, motor current increases (torque is proportional to current) so back EMF and therefore speed must decrease. Efficiency

drops rapidly to zero (at stall). In addition to the direct disadvantage of inefficiency, there are problems of control circuitry with high current output capability, and decreased motor life due to field demagnetization.

For details, see appendix A.

d) Insufficient Rigidity in Above Elbow Section

To achieve the feedback gain required in volts per in.-lb. of bending moment, the upper arm section on which the feedback strain gauges are mounted is very thin. This results in a low safety factor which would not be permissible in a production item. The section would be expected to yield if a load of 15 lb. were lifted. Also the upper arm section has too low a spring rate in bending, causing inappropriate dynamics under some conditions.

For details, see appendix C.

e) Backlash

There is about an inch of backlash at the terminal device, due primarily to tolerances in the thrust bearing assembly, ball screw, and bushings, which are magnified by the geometry. This backlash was expected to increase with

time as the Delrin AF plastic bushings in the elbow, forearm, and upper arm pin joints wear, but wear has not been a problem and backlash has not increased significantly.

II. Design Advantages

a) Continuous Self Locking

The device is self locking due to the inclusion of the R=L clutch. This feature combined with the force feedback results in a system in which the operator is required to flex his muscle and provide an EMG input to hold an external load. This approximates the situation with a normal arm. At the same time no current is supplied to the motor to produce the sustaining torque (as this is provided by the clutch), since the error signal is near zero, within the forward loop deadband.

For details, see appendices A and D.

b) Efficient Drive Train

The self locking feature is not unique in prosthetic applications as nearly all devices to date have used a worm gear or screw actuator, although without force feedback. The difference

is that drive train efficiency has been in all cases between 7-20%. The 20% efficiency has been achieved only with non-standard, special helix angle screws. This efficiency figure includes the entire drive train, excluding the motor or other actuator. The drive train efficiency in the device described here is 60-65%, as a non-locking ball screw was used, relying on the R-L clutch for the selflocking feature.

c) High Speed and Load Capability

While the motor used is a standard one, widely used in prosthetic devices, the efficient drive train allows a level of performance not previously available. Flexion time with no external load is under 3/4 second. Speed decreases as load increases, and the load at stall is about 10 lb. at the terminal device (with a 2 ohm resistor in series with the motor to prevent excessive current at stall).

For details, see appendix G.

d) Use of Standard Components

In the interest of economy, standard, as opposed to custom or home-made components were used throughout. This includes the motor,

clutch, screw, strain gauges, and several amplifiers and smaller components.

The only serious mismatch was the clutch. As a standard industrial unit, this is rated at 90 in.-lb. torque, while only 5 at the most is required. The excess capacity in itself is not a problem, but the device weighs almost a pound.

The use of standard components has kept the cost of the prototype within reason.

For details, see appendix B.

e) Performance Criteria Satisfied

The system is compatible with EMG derived input and works reliably. Feedback functions well and the arm motion and load dependence approximates that of a non-locking device with viscous damping. Frequency response is increased by the presence of the clutch. However, this effect is nonlinear and step response is unaffected. Actuator performance is satisfactory, except that efficiency falls off at higher loads.

CHAPTER THREE

RECOMMENDED MODIFICATIONS

a) The Clutch

As has been mentioned, the reverse locking clutch used is a standard unit with torque capacity in excess of the requirement and weighs nearly a pound. Since it is absolutely essential to reduce the device's weight by nearly a pound, this would be a good place to start. This unit is the smallest in the line of reverse locking clutches offered by Formsprag, Inc. Other R-L clutches are available from other manufacturers, with torque ratings down to 35 in.-lb., but with no saving in size or weight, so these need not be considered.

One possibility is to have ~~des~~igned and manufactured a special purpose miniature version of the R-L clutch. This is a relatively expensive solution.

Also, there is the possibility of using an efficient, non locking screw which, in series with the gear reducer and it's attendant dry friction, would behave as though locked with loads under a critical value. This does not seem practical with a ball screw. Non-locking

acme screws with teflon on steel can be from 81-93% efficient, given the right helix angle. However, to achieve this efficiency in an acme screw, helix angles of 35° or more must be incorporated, so this does not seem practical either. Clearly this approach, if it could be made to work, would be the lightest, smallest, and most economical, and therefore it warrants further consideration.

A third alternative is a brake with a solenoid or other actuator which would lock the drive train when the error signal is within the deadband. Since this can be purchased as an optional feature on many motors, cost would not be prohibitive. The braking would take place on the motor end of the gear reducer, so the torque involved is light and the unit may be small and light. However, the power consumption may be prohibitive, and the system would become more complex.

There are no doubt other possibilities not considered here, and the solution will determine how practical the device ultimately will be.

b) Mechanical Impedance Adjustment

It would be advantageous for a number of reasons to keep the motor at nearly constant speed over a wide range of loadings. As prosthetic devices are presently conceived, this is impossible since a higher torque necessitates more current, therefore less back EMF, therefore slower operation. Advantages of a nearly constant speed system would be:

- 1) greater efficiency (smaller power pack)
- 2) smaller motor required
- 3) lower current and power capacity in control circuitry; smaller components
- 4) less expensive components throughout
- 5) greater load capacity in the arm
- 6) longer motor life

A solution to this problem would serve very much the same purpose as an automobile transmission, keeping the engine within it's permissible speed range although vehicle speed may vary by a factor of 100. Because the PM motor cannot operate well over a wide range, three speeds would not suffice, and clearly the transmission must be automatic.

c) Rigid Above Elbow Section

The above elbow section on which the feedback strain gauges are mounted was made very thin in order to achieve the required feedback gain. The structural safety factor is very low there and the low spring rate of the section in bending causes some undesirable dynamics. In subsequent models this section should be made more rigid, which will then necessitate either semiconductor strain gauges, or high gain amplifiers with the wire gauges used here, to achieve the required gain.

d) Redesign of Power Amplifier

There are three basic types of circuit in the controls; a differential amplifier and a ± 15 volt power supply, both of which are quite reliable, and a power amplifier, the performance of which is less than ideal. It was designed as a dissipative type but usually operates as a switching amplifier. Sometimes it is dissipative; the mode of operation seems to be related to ambient temperature. Deadband in the first stage causes erratic operation near zero, and the output drifts.

While further development of this amplifier

might be successful, it would be considerably less expensive to begin again on a switching amplifier by intent, and by an experienced circuit designer.

e) Backlash

There is about an inch of backlash at the terminal device. This is due primarily to tolerances in the thrust bearing assembly, screw actuator, and bushings. Our experience has been that extrusion of the Delrin AF bushings is not a problem, and friction is very low. These seem satisfactory. Greater care should be taken in the design of the thrust bearing assembly and selection of the screw actuator in order to reduce axial tolerances.

f) Limit Switches

It was originally felt that mechanical constraint of the motion of the arm was sufficient in the laboratory model and, under these controlled conditions, limit switches would not be necessary. However, one burned out motor later, it is apparent that limit switches would be a desirable addition to all subsequent models, for laboratory or clinical use.

CHAPTER FOUR

SUMMATION

An electric elbow and associated controls have been designed and built for EMG control. The device performs satisfactorily. Overall weight is slightly over 2 lb., which is more than desirable. Possible areas for miniaturization have been investigated, such as the reverse locking clutch which provides the continuous self locking feature. Minimum flexion time is under 3/4 sec. and maximum elbow torque at stall is 120 in.-lb.

The device is compatible with long upper arm stumps as all drive equipment is located in the forearm section. However, this causes an excessive inertia about the elbow.

The self locking feature, together with force feedback provided by a strain gauge bridge results in no electric power being required to hold a load.

The device is relatively efficient, except when high loads cause the motor to operate in an inefficient range. Power supply is from nickel-cadmium batteries or a plug in DC supply. Low friction elements such as the ball bearing screw actuator are used exclusively in the drive train.

The internal control system provides force feedback from the strain gauge bridge and velocity feedback from the motor back EMF. Force feedback is required to provide the holding action with no power described above. Velocity feedback eliminates jerky motion due to starting friction.

A permanent magnet motor was used as it combines high power in a small package with high efficiency over a reasonable range. This type motor, however, is not ideally suited to high torque outputs near stall and its life may be shortened considerably.

$$\frac{dE_1}{6\phi f D / E t^2 l} = E_0 / 2$$

$$dE_1 / f = g / 2 = 3\phi D E_0 / E t^2 l$$

$$g = 6\phi D E_0 / E t^2 l \text{ v./lb. (force)}$$

$$t^2 l = \frac{6M}{S_m} = 6f_m D / S_m$$

$$g = \phi E_0 S_m / E f_m$$

Appendix D

Dynamic Analysis

I_2 =moment of inertia of forearm section about
it's C.G.=(3.5×10^{-2})lb.-in.-sec.²

m =mass of forearm section=(5.2×10^{-3}) $\frac{\text{lb.-sec.}^2}{\text{in.}}$

l =distance from elbow joint to C.G.=7"

M =load mass (at terminal device)

L =overall length of forearm section=12"

c =viscous friction in arm=(.01) in.-lb.-sec.

ϕ =angular motion of arm

T_2 =torque about elbow

d =viscous friction of load

k =mechanical transformer ratio $T_2/T_1=28.2$

T_1 =torque on ball screw

e =ball screw position(angular)

$k_2 = \frac{\text{torque}}{\text{volts}}$ of motor in series with 2 ohm resistor=.22

E =applied voltage

J =moment of inertia of clutch & screw=(7×10^{-6})lb.-in.-sec.²

r =gear ratio=18.8:1

I_1 =armature moment of inertia=(3.3×10^{-6})lb.-in.-sec.²

b =drive train damping(back EMF & friction)=(4.8×10^{-2})lb.-in.-sec.

k_3 =mechanical transformer ratio $\frac{\text{force}}{\text{torque}}$ for ball screw
=50.2 lb./in.-lb.

f =force on ball screw

Nonlinearity due to saturation is neglected except in limit cycle evaluation. Gravity is neglected as a constant bias for small motions.

the equation of motion of the arm is:

$$(I_2 + ml^2 + ML^2)\ddot{\phi} + (c+d)\dot{\phi} + k\phi = T_2 \quad (1)$$

looking at this relationship from the drive train instead of the arm:

$$(I_2 + ml^2 + ML^2)\ddot{\theta} + (c+d)\dot{\theta} + k\theta = T_1 k_1^2 \quad (2)$$

the equation relating torque to applied voltage is:

$$T_1 = k_2 E - (J + r^2 I_1)\ddot{\theta} = b\dot{\theta} \quad (3)$$

rearranging (2):

$$\theta = \frac{k_1^2 T_1}{(I_2 + ml^2 + ML^2)s^2 + (c+d)s + k} \quad (4)$$

combining (3) & (4):

$$T_1 = k_2 E - k_1^2 T_1 \frac{(J + r^2 I_1)s^2 + bs}{(I_2 + ml^2 + ML^2)s^2 + (c+d)s + k} \quad (5)$$

rearranging (5) and substituting $f = k_3 T_1$:

$$\frac{f}{E} = k_2 k_3 \frac{(I_2 + ml^2 + ML^2)s^2 + (c+d)s + k}{(I_2 + ml^2 + ML^2 + k_1^2 J + k_1^2 r^2 I_1)s^2 + (c+d + k_1 b)s + k}$$

incorporating this relation in the overall system:

A=electrical forward loop gain=360 volt/volt

$\frac{f}{E}$ =mechanical forward loop gain= C/D

B=feedback gain=(1.8×10^{-2}) volts/lb.

$$H = \frac{AC}{D+ABC}$$

$$H = \frac{(360) \frac{1}{I_2 + ml^2 + ML^2} s^2 + (c+d) s + k_2 k_3}{(I_2 + ml^2 + ML^2 + k_1^2 J + k_1^2 r^2 I_1) s^2 + (c+d+k_1 b) s + k_1 + (360)(1.8 \times 10^{-2}) k_2 k_3 \frac{1}{I_2 + ml^2 + ML^2} s^2 + (c+d) + k_1}$$

Nyquist plots of this transfer function are presented for no load and for $k=100$ lb./in., the approximate spring rate of a normal hand. In both cases $M=2$ lb.(weight). See figures 7 & 8.

Since the nonlinearity is amnesic, the function $-\frac{1}{K_{eq}}$ (K_{eq} =equivalent gain of the nonlinearity) lies along the negative real axis of the plot and cannot intersect with the linear Nyquist characteristic. Therefore there is no limit cycle.

Care should be taken in the design of control circuitry to keep phase shift to a minimum, as excessive phase shift could cause a limit cycle.

TOLERANCES $\pm \frac{1}{64}$

Differential Amplifier

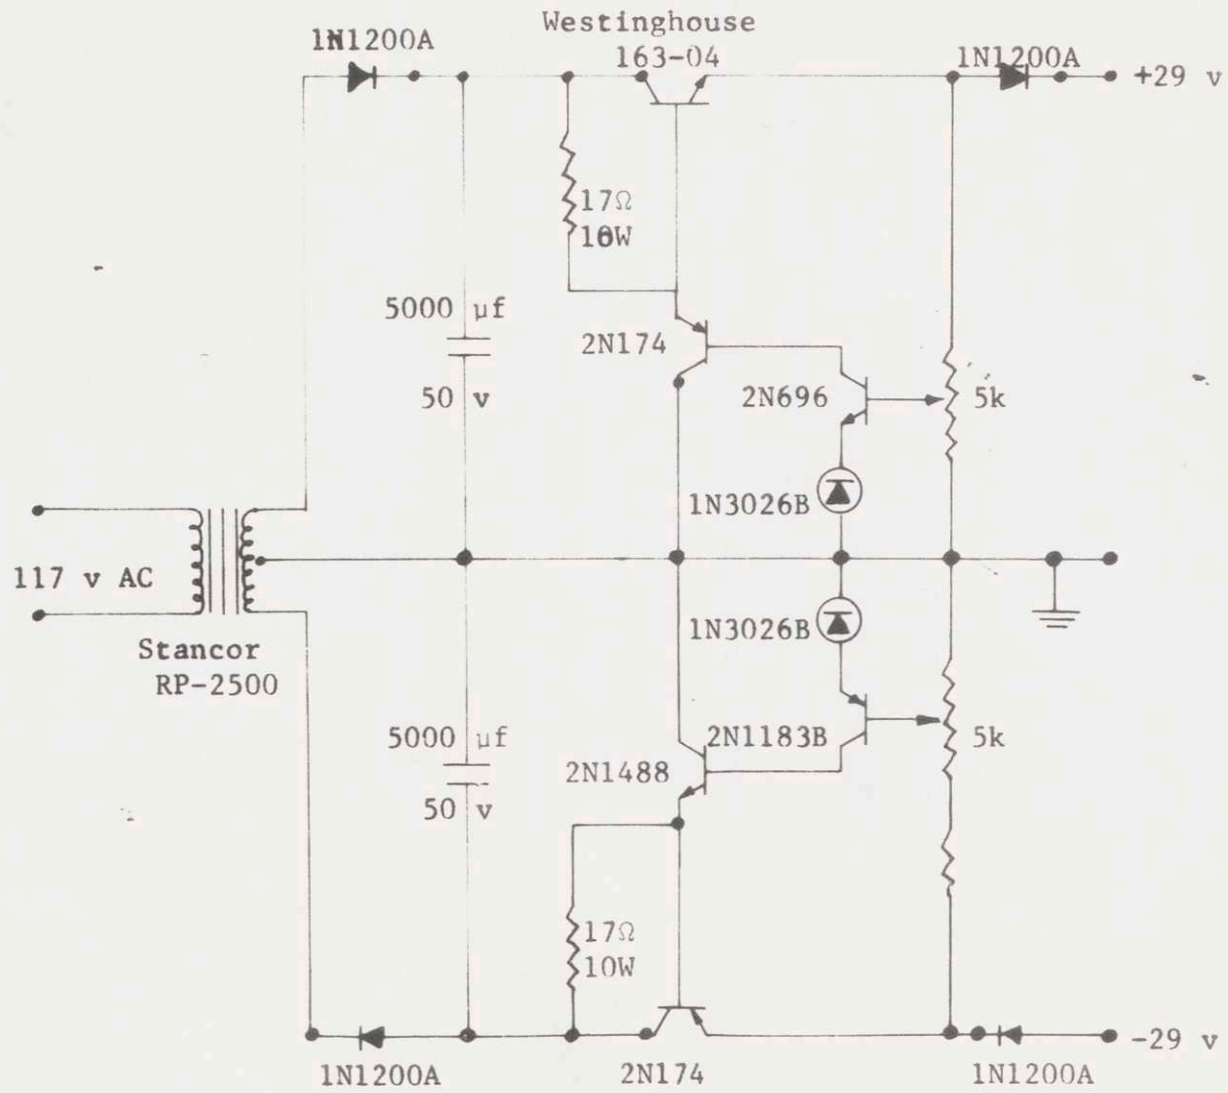

Power Amplifier

gain = $75 \frac{\text{volts}}{\text{volts}}$

current output 8 amps (max.)

Strain gauge and differential amplifier power supply
 current output 50 ma.

Power supply and
battery charger
(not intended to
be portable)

8 amps max.

Appendix F

Relevant CPRD-NAS criteria

- (A) 12 volt electrical systems should be standard.
- (B) The maximum weight of the power pack should not exceed 2 to $2\frac{1}{2}$ lb.
- (N) A powered elbow should have a continuous lock and a minimum active torque of 100 in.-lb.
- (O) It was desirable but not essential for the elbow to have a free swinging capability.
- (P) The elbow's range of flexion should be from 10° to 135° .
- (Q) The elbow's flexion speed with no load, from maximum extension to maximum flexion, should not be more than 2 seconds.
- (R) The elbow should have a holding torque of 600 in.-lb. at 90° flexion of the elbow, unless the device is capable of withstanding 1500 in.-lb. of destructive torque.
- (AB) The device should not weigh more than 60% of the limb it replaces.

Appendix G

Actuator Characteristics

figure 9

Actuator Characteristics

figure 10

This plot is indirectly a measure of motor life vs. resistance in series with the motor. 180 in.-lb. elbow torque is possible with no resistance. With $R=2$ ohms, elbow torque $T=120$ in.-lb.(max.)

figure 11
